# Factors affecting photocatalytic performance through the evolution of the properties due to the phase transition from $NaBiO_3 \cdot 2H_2O$ to $BiO_{2-x}$

**Abstract**  The phase transition process of a photocatalytic system from $NaBiO_3 \cdot 2H_2O$ to $BiO_{2-x}$ has been investigated to understand the important factors that affect photocatalytic performance in a composite system. It is found that a proper amount of $BiO_{2-x}$ on the surface of $NaBiO_3 \cdot 2H_2O$ could effectively suppress the electron/hole recombination and increase the exposed reactive sites for photocatalytic reaction. A fully covered $BiO_{2-x}$ on $NaBiO_3 \cdot 2H_2O$ results in a dramatical decrease of photocatalytic degradation of dye. An over long hydrothermal process can result in $BiO_{2-x}$ with reduced oxygen vacancies, which degrades the photocatalytic activity. Furthermore, the photocatalytic reduction ability of $CO_2$ conversion has been investigated, indicating that the surface activity to different reactants also directly affects the catalytic performance. The investigation of the gradient phase transition process presents a clear guidance to construct a desired photocatalytic system, in addition to selecting gradient materials with suitable bandgap structure and a morphology with different fraction and distribution of each component. The defect evolution of each component during construction of a composite is also an important factor that should be optimized and considered in making a composite to achieve high photocatalytic efficiency.

**Keywords**  composite construction, distribution, $BiO_{2-x}$, evolution of defects

## 1  Introduction

Due to the fast increase of the global energy consumption, solutions to relieve the server environmental pollution and energy has become an urgent need worldwide. Among various possible approaches, the water splitting, adsorption, and decomposition or conversion of pollutants into non-toxic or even useful fuels by using (photo)catalysts has been considered as promising directions [1–11].

In addition to $TiO_2$ or the single-phase photocatalytic system, many photocatalytic composite systems have been reported as potential strategies with efficient photocatalytic abilities, such as $g-C_3N_4$, bi-based nanomaterials, and various oxide semiconductors based composite system [12–19]. A majority of photocatalytic systems have been built by constructing two or more separated phased in a physical or hydrothermal process to investigate effective factors. However, most of the factors have been focused on the fraction and distribution of each component and the bandgap structures, but the property evolution of each component during coupling process has been ignored because usually no obvious change is presented in X-ray diffraction (XRD) or Fourier transform infrared spectrometer (FT-IR). Hence, to clearly understand the effective factors, constructing a heterojunction structure formed *in situ* should be the main choice, and *in situ* phase transition induced by calcination or doping have been used to construct such kind of composites [20–23]. Hydrothermal reaction has been explored to control the process of *in situ* phase transition. The phase transition from $NaBiO_3 \cdot 2H_2O$ to $BiO_{2-x}$ has been selected, due to the suitable band structures between $NaBiO_3 \cdot 2H_2O$ and $BiO_{2-x}$, and the gradient transition from $NaBiO_3 \cdot 2H_2O$ to $BiO_{2-x}$ could be regarded as an *in situ* (formation of a new gradient in the composite from the initial phase) growth of $BiO_{2-x}$ at the surface of $NaBiO_3 \cdot 2H_2O$. The remaining $[BiO_2]^-$ parts in $NaBiO_3$ could be easily transformed to $BiO_{2-x}$ after removal of $Na^+$ ions during a hydrothermal reaction

[24]. Furthermore, it is easy and convenient to investigate the evolution of $BiO_{2-x}$ during the transition process.

The bandgap energy of $BiO_{2-x}$ is about 1.6 eV [25], which extends the absorption range to visible and near-infrared light (NIR). In addition, since the oxygen defective $BiO_{2-x}$ possesses a 2D-like lattice structure, the oxygen vacancies can have more and stronger interactions with $O_2$ to form reactive oxygen species ($O_2^{-\bullet}$), and the oxygen defective content has been reported to have a determinant effect on the photocatalytic activity of $BiO_{2-x}$ [25,26]. Mostly, the $BiO_{2-x}$ phase is produced from the conversion of $NaBiO_3 \cdot 2H_2O$, and $NaBiO_3 \cdot 2H_2O$ itself is also a visible light photocatalyst with a bandgap of approximately 2.5 eV and suitable energy band positions [27]. The overpotentials of both $NaBiO_3 \cdot 2H_2O$ and $BiO_{2-x}$ than $O_2/(-0.13$ eV versus (normal hydrogen electrode) NHE) makes such composite more efficient to generate highly oxidizing superoxide ($O_2^{-\bullet}$), which can effectively decompose dye pollutants [28]. Various $BiO_{2-x}$ based heterojunctions, such as $Bi_2O_2CO_3/graphene/BiO_{2-x}$, $BiO_{2-x}/Bi_2O_{2.75}$, $Bi_2O_4$-$Bi_4O_7$-$BiO_{2-x}$, core-shell-structured $Bi_2O_4/BiO_{2-x}$, $BiO_{2-x}/NaBiO_3$ etc., have been proposed as highly efficient photocatalysts [29–33]. However, the conclusions only focus on the enhanced light absorption and charge separation efficiency with suitable band structures.

Through the study of gradient transition from $NaBiO_3 \cdot 2H_2O$ to $BiO_{2-x}$ by using a hydrothermal method with variation of the reaction time and the characterizations of the structural, optical, and photo-electrochemical properties, the results reported here could provide systematic information on the construction of photocatalytic composite systems. The factors affecting the photocatalytic performance have been determined by the orderly changes in the degradation efficiency of methyl orange. Finally, to investigate the photocatalytic reduction abilities, the measurements of photocatalytic $CO_2$ reduction in a solid/gas system have been conducted.

## 2   Experimental section

### 2.1   Materials

All of the chemicals for the synthesis of the catalysts were used without any further purification. Sodium bismuthate ($NaBiO_3 \cdot 2H_2O$, $w(NaBiO_3 \cdot 2H_2O) > 80\%$, $w$ is mass fraction), sodium hydroxide beads (NaOH, $w(NaOH) > 97\%$, $w$ is mass fraction) and methyl orange (MO) were purchased from the DAEJUNG company.

### 2.2   Synthesis of $NaBiO_3 \cdot 2H_2O$ (NBH)/$BiO_{2-x}$

The NBH/$BiO_{2-x}$ composite and $BiO_{2-x}$ were prepared by a hydrothermal method. 1 g of NBH was put into 30 mL of deionized (DI) water, then mixed with 20 mL of 1.6 mol/L NaOH solution for 1 h. The mixture was transferred to an 80 mL Teflon vessel sealed in a stainless autoclave and heated at 180°C for a certain time, and labeled as NB-$x$ ($x$ is the reaction time: 0, 1.5, 3, 5, 6, 7.5, 9, 12, 16, 21 h). After being cooled down in air to room temperature, the products were washed using DI water and ethanol, then dried in air at 60°C for 12 h. To investigate the effect of pH value (alkaline, neutral, and acidic conditions) during the synthesis process, deionized water or dilute nitric acid solvent (addition of 3 mL concentrated $HNO_3$) was also used instead of NaOH. The XRD and scanning electron microscopy (SEM) images of these samples were presented in Fig. S1 in Electronic Supplementary Material (ESM).

### 2.3   Characterizations

The crystal structures of the samples were characterized by a Rigaku MiniFlex 600 XRD using Ka ($\lambda = 0.15428$ nm) radiation. FT-IR was recorded using a Nicolet Avatar 370 FT-IR to investigate the chemical bonds. The morphologies and elements distribution were characterized by SEM (Hitachi-S4800) and transmission electron microscopy (TEM) equipped with energy dispersive spectrometer (EDS) (JEOL, JEM-ARM200F). The X-ray photoelectron spectroscopy (XPS) characterizations were measured by using a monochromated Al Ka X-ray source ($hv = 1486.6$ eV) at 15 kV/150 W to investigate the evolution of ion valence (Busan Center of Korea Basic Science Institute). The UV-vis diffuse reflectance spectra (UV-vis DRS) were performed on a U3010 UV-vis spectrometer to identify the visible light absorption ability and NIR absorption. The photoluminescence (PL) emission spectra were recorded with an excitation wavelength of 320 nm. The surface photovoltage (SPV) measurement was conducted on a surface photovoltage spectroscopy (CEL-SPS 1000, Beijing Perfect Light Technology Co., Ltd).

## 3   Results and discussion

The XRD patterns and FT-IR spectra are shown in Figs. 1(a) and 1(b). In Fig. 1(a), the spectrum labeled with a, b, c, d, e, f, g, h, i, and j presents the sample NB-0, NB-1.5, NB-3, NB-5, NB-6, NB-7.5, NB-9, NB-12, NB-16, and NB-21, respectively. The purchased NBH is used as NB-0. Obviously, NB-1.5–NB-9 exhibit two sets of XRD peaks from NBH and $BiO_{2-x}$, and the peak intensities of $BiO_{2-x}$ are enhanced with the reaction time, suggesting continuous conversion from $Bi^{5+}$ to $Bi^{3+}$. In NB-12, NB-16, and NB-21, all the diffraction peaks are matched well with the cubic phase of $BiO_{2-x}$ (JCPDS NO. 47-1057), indicating that all NBH has been converted to $BiO_{2-x}$ after 12 h of reaction.

The FT-IR characterization demonstrated a consistent phase transition with the XRD spectra. As displayed in
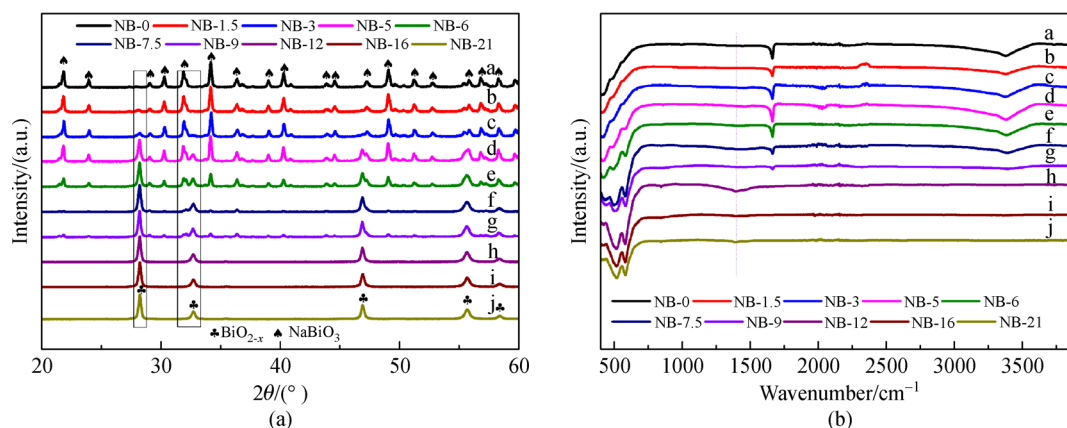

**Fig. 1**  XRD patterns and FT-IR spectra of samples obtained at different times (a. NB-0 0 h, b. NB-1.5 1.5 h, c. NB-3 3 h, d. NB-5 5h, e. NB-6 6 h, f. NB-7.5 7.5 h, g. NB-9 9 h, h. NB-12 12 h, i. NB-16 16 h, j. NB-21 21 h).
(a) XRD patterns of samples; (b) FT-IR spectra of samples.

Fig. 2, NB-0 (curve a) exhibits characteristic peaks at 418, 482, and 566 cm$^{-1}$, which can be ascribed to the typical stretching vibration of bonds in BiO$_6$ octahedral units [34]. The broad peaks at 1620 and 3400 cm$^{-1}$ can be assigned to the stretching vibration mode of –OH. NB-12 (curve h) only reveals two strong peaks at 519 and 584 cm$^{-1}$ [35], which can be attributed to the Bi–O bonds in BiO$_3$ pyramidal units. NB-1.5–NB-9 (curves b–g) exhibit two sets of FT-IR peaks as a combination of NBH and BiO$_{2-x}$, with a gradual increased intensity from BiO$_{2-x}$. Interestingly, a quite obvious peak located at 1493 cm$^{-1}$ only appears in NB-12, which can be attributed to the abnormal bond caused by the high density of oxygen vacancies in BiO$_{2-x}$ [36,37]. However, this peak becomes quite weak

again in NB-16 and NB-21, implying that the oxygen vacancies could be filled up with a longer reaction time.

The phase transition from NBH to BiO$_{2-x}$ can also be clearly observed from the morphology change of the products. NB-0 shows worm like aggregated particles composed of irregular nanosheets (Fig. 2(a)), and BiO$_{2-x}$ shows a wall-like nanostructure made up of hexagonal nanoplates mostly perpendicular to each other (NB-12 to NB-21) [38]. The worm-like morphology is maintained till NB-6, indicating the dominant composition of NBH in the composite. It is expected that BiO$_{2-x}$ is formed from the NB-0 surface during the hydrothermal reaction. It can be seen in the high-resolution image of NB-1.5 (Fig. 2(b)) that there are some small and tiny plates of BiO$_{2-x}$ on the

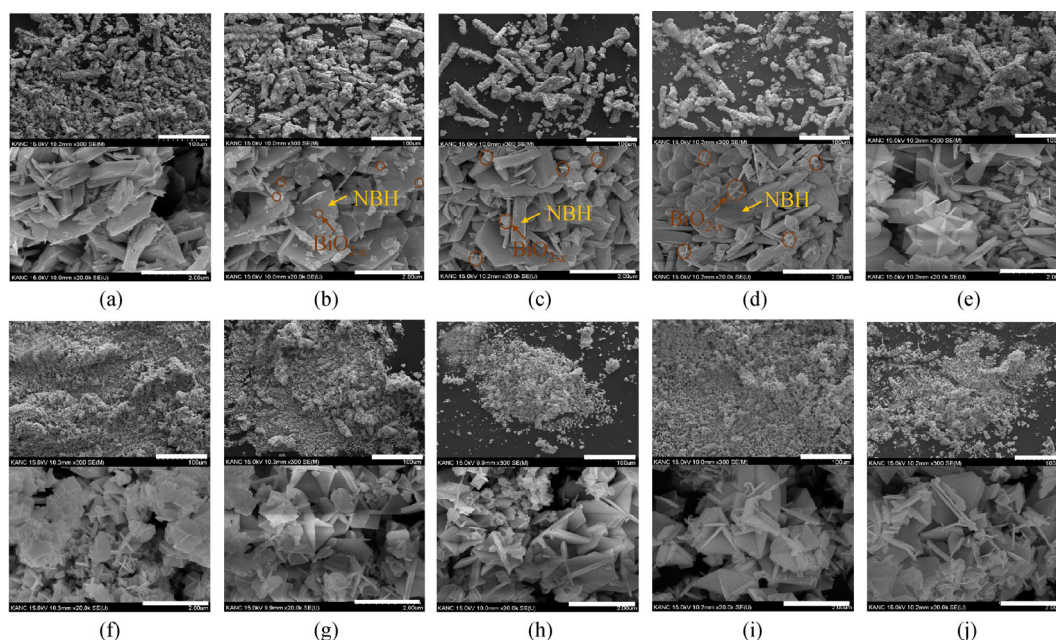

**Fig. 2**  SEM images of reaction time dependent samples (longer scale bar: 2 μm; short scale bar: 100 μm).
(a) NB-0; (b) NB-1.5; (c) NB-3; (d) NB-5; (e) NB-6; (f) NO-7.5; (g) NB-9; (h) NB-12; (i) NB-16; (j) NB-21.

surface, and more and larger $BiO_{2-x}$ nanoplates in NB-3. In NB-6, abundant $BiO_{2-x}$ plates appear and cover most parts of the NBH surface. From NB-7.5 to NB-21, the worm-like structure disappears, indicating that $BiO_{2-x}$ becomes the dominant material in the composite.

The microstructures of NB-3, NB-6, and NB-12 measured by TEM are depicted in Fig. 3. In NB-3 (Fig. 3(a)), tiny and small hexagonal $BiO_{2-x}$ nanoplates are formed on the surface of irregular shaped NBH nanoparticles. In NB-6, it is not easy to observe NBH, which should be mostly covered by larger $BiO_{2-x}$ plates (Fig. 3(b)). The TEM of NB-12 shows larger hexagonal $BiO_{2-x}$ nanoplates (nm) with sharp edges. The EDS-elemental mapping images and the corresponding elements ratio are collected in Fig. 4 and Table 1, respectively. A homogeneous distribution of Bi, O, and Na elements can be seen in all three samples. Table 1 shows that the percentage of Na element and the atomic ration (O/Bi) decreases with the reaction time till NB-12, implying the continued phase transition from NBH to $BiO_{2-x}$. The very low percentage of Na in NB-12, which could be attributed to the trace residual on the surface after washing, can be ignored. It is noted that the O/Bi atomic ratio in NB-16 is larger than the NB-12, most probably due to the filling of oxygen atoms into the oxygen vacancies caused by a longer reaction time, that is to say, NB-12 has more oxygen vacancies.

XPS characterization was performed on NB-0, NB-3, NB-6, and NB-12 to determine the specific bonding and the chemical states of the elements on the surface of the composition during the phase transition. The XPS wide scan spectra in Fig. 5(a) clearly demonstrate the existence of the Na, Bi, and O elements, and the percentage of each element is listed in Table 1 and the details in Table S1 (in ESM). The evolution tendency of the ratio between different elements are consistent with the EDS results listed in Table 1. Interestingly, the increasing atomic ratios of O/Bi from NB-6 to NB-21 indicate an increase of the oxygen concentration in $BiO_{2-x}$, i.e., some of the oxygen vacancies are filled, which may be mainly caused by the $O_2$ generated during the phase transition process (equations in ESM). In the EDS measurement, the relative atomic ratio of O/Bi in $BiO_{2-x}$ is smaller than that obtained from XPS. For the sample of NB-16, the two results from EDS and

XPS are similar, therefore, it is speculated that the filling of oxygen vacancies is mainly a process from the surface of the sample to the inside. As shown in the high-resolution spectrum of C 1s in Fig. 5(b), only one clear peak appears at 284.6 eV in each sample due to the carbon impurities, and is taken as a standard reference for calibration [39]. High-resolution XPS curves of Bi 4f shown in Fig. 5(c) show an obvious peak evolution with the reaction time. Only two peaks at 158.45 and 163.80 eV can be observed in NB-0, which belong to the peaks of Bi 4f7/2 and Bi 4f5/2 of $Bi^{5+}$. In NB-3, NB-6, and NB-12, the peaks of Bi 4f can be de-convoluted well into four peaks at binding energies of 158.05, 163.35 eV, 158.45, and 163.80 eV, representing the $Bi^{3+}$ and $Bi^{5+}$ chemical states, respectively [40]. Obviously, the splitting of Bi 4f peaks with respect to the reaction time indicate an increased percentage of $Bi^{3+}$ chemical state due to the appearance of $BiO_{2-x}$. In the case of O 1s state shown in Fig. 5(d), the peaks can be deconvoluted into three peaks with binding energies of 529.24, 530.70, and 533.83 eV for the sample of NB-0, which are attributed to the lattice O in crystal, oxygen vacancy and absorbing water or crystal water [29]. Depending on the reaction time, the strongest peak at around 529.24 eV shifts to a lower binding energy due to the change in the O bonds environment induced by the phase transformation from NBH to $BiO_{2-x}$ (the transformation of $Bi^{5+}$-O to $Bi^{3+}$-O). In addition, the intensity of the peak at 533.83 eV decreased, due to the loss of crystal water during the hydrothermal reaction, which is consistent with the investigation of FT-IR. Obviously, the peak intensity at 530.7 eV increases from NB-0 to NB-12, indicating the continue formation of oxygen defective $BiO_{2-x}$. $BiO_{2-x}$ has an oxygen defective structure. Oxygen defects can cause changes in the structural environment of the surrounding lattice oxygen, mainly resulting in increased electron density of the surrounding oxygen, thereby the binding energy (529.10 eV) of part initial oxygen shift to a higher binding energy (530.70 eV). In general, this peak next to that of lattice oxygen is often used to indicate the strength of oxygen defects [41,42]. Furthermore, the high-resolution XPS spectra of O 1s and Bi 4f for the samples from NB-12 to NB-21 are shown in Fig. 6. No obvious difference can be observed, however,

**Table 1** Elemental ratio measured by EDS and XPS for NB-3, NB-6, NB-12, and NB-16

| Element | NB-3/(Atomic fraction, %) | NB-6/(Atomic fraction, %) | NB-12/(Atomic fraction, %) | NB-16/(Atomic fraction, %) |
|---|---|---|---|---|
| O (EDS) | 56.73 | 61.41 | 50.28 | 55.06 |
| Na (EDS) | 17.15 | 8.64 | 2.99 | 3.05 |
| Bi (EDS) | 26.13 | 29.96 | 46.74 | 41.90 |
| Total: (EDS) | 100.00 | 100.00 | 100.00 | 100.00 |
| Atomic ratio: O/Bi (EDS) | 2.17 | 2.05 | 1.08 | 1.31 |
| Atomic ratio: O/Bi (XPS) | 1.49 | 1.32 | 1.31 | 1.34 |

the peaks of Bi 4f from NB-12 to NB-21 slightly shift to a lower binding energy, indicating that tiny of $Bi^{5+}$ changed to $Bi^{3+}$, as shown in Fig. 6(a). Besides, the intensity of the peak induced by oxygen vacancy decreases slightly, indicating that the content of defect is decreasing, as shown in Fig. 6(b). The investigations from XPS are consistent with the characterizations in the XRD and EDS measurements. The above characterizations reveal a clear view of structure and morphology change during the *in situ* phase transition from NBH to $BiO_{2-x}$, which is expected to affect the photocatalytic properties.

UV-vis DRS were taken from the samples to evaluate their optical properties, as presented in Fig. 7(a). The visible light absorption between 400 and 800 nm clearly
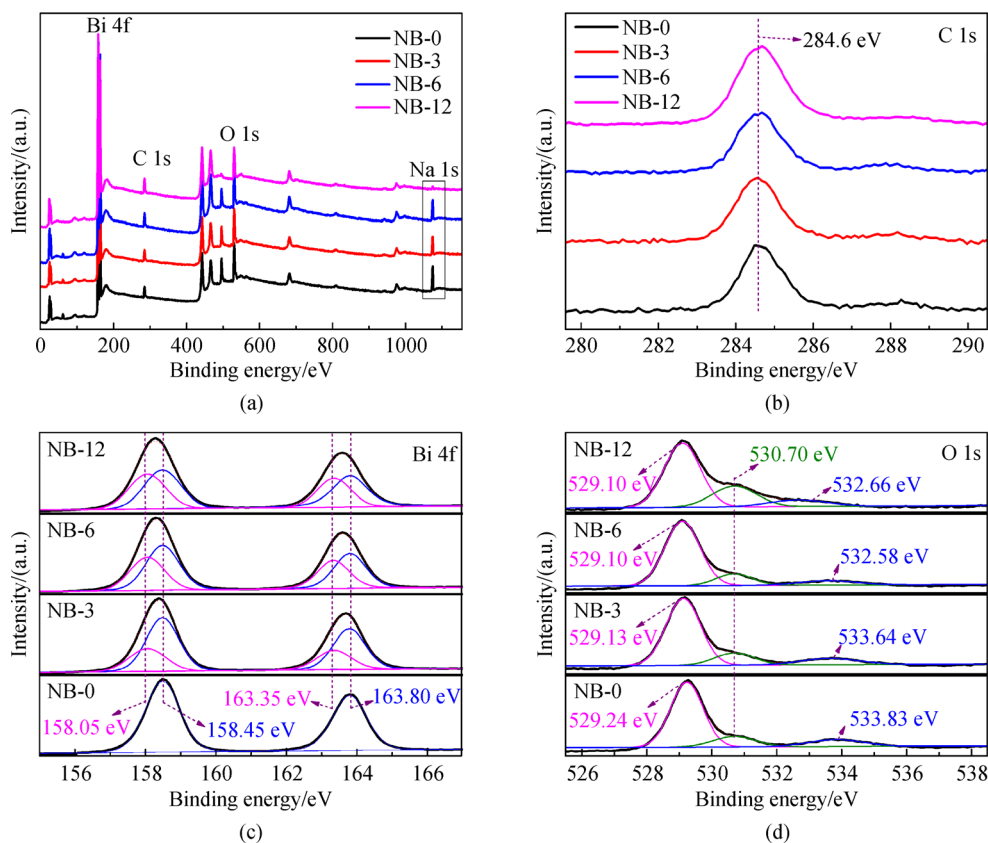

**Fig. 5**  XPS spectra of NB-0, NB-3, NB-6 and NB-12.
(a) Survey scan; (b) high-resolution C 1s; (c) Bi 4f; (d) O 1s.

(a) Bi 4f; (b) O 1s.

increases with the reaction time, which should be attributed to the increase of the percentage of $BiO_{2-x}$ in the composite. Accordingly, $BiO_{2-x}$ (NB-12, NB16, and NB-21) shows a much higher visible light absorption than other samples. On the other hand, detailed inspection reveals that NB-12 has the highest visible light absorption efficiency (upper panel in Fig. 7(b)), which should be attributed to the highest oxygen vacancy density in this sample. It has been

reported that the oxygen vacancy could produce a defect energy level to enhance the light adsorption [43–46].

In the longer wavelength range between 900 and 1200 nm, the light absorption shows a quite different dependence on the composition (lower panel in Fig. 7(b)). It is seen that NBH has a better absorption than $BiO_{2-x}$, and accordingly, the longer wavelength light absorption decreases continuously as the amount of $BiO_{2-x}$ increases
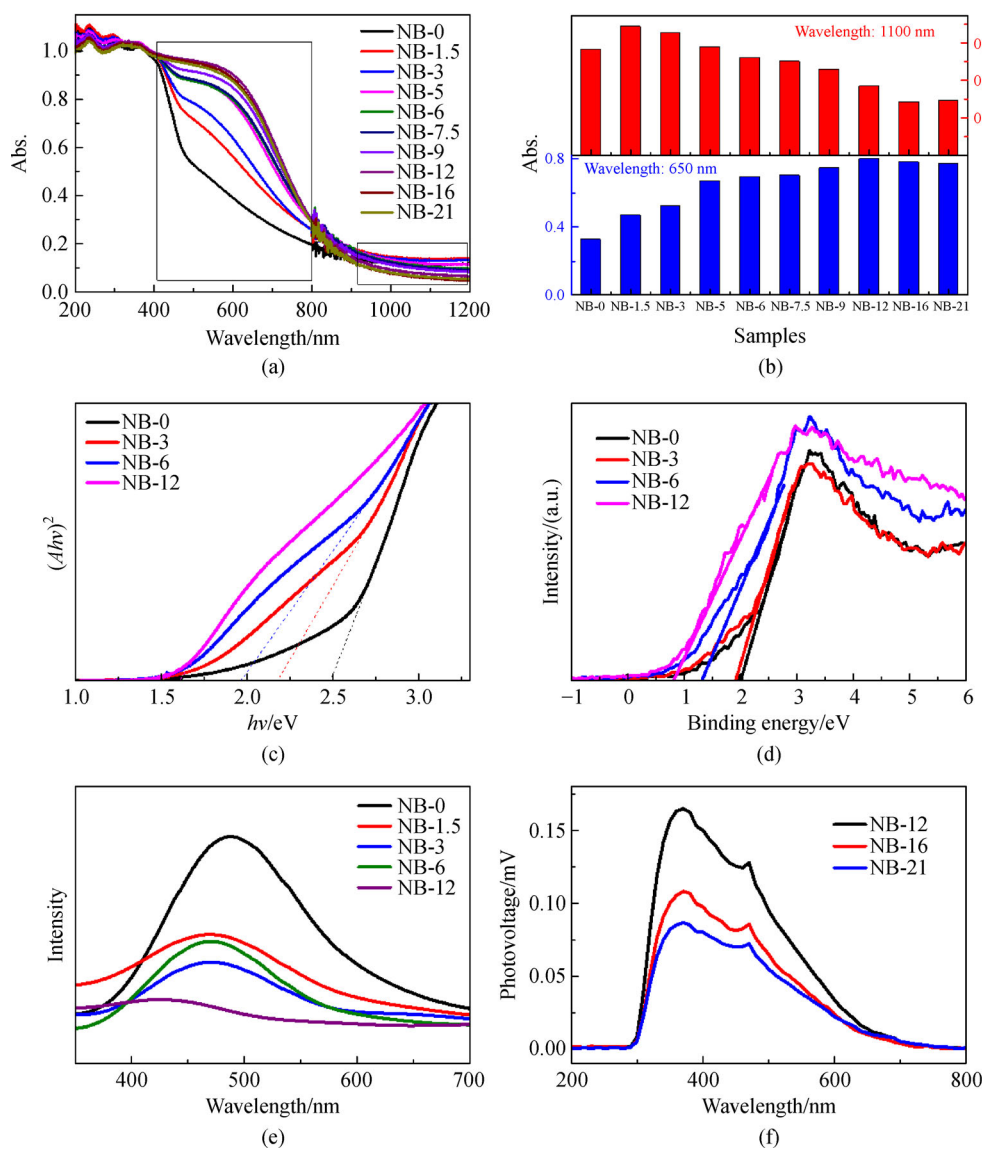

**Fig. 7**  Optical properties of a series of reaction time dependent samples.

from the NB-1.5 sample. Interestingly, the obvious enhancement of the light absorption in NB-1.5 or NB-3 as compared with NB-0 could be probably due to the rich oxygen vacancies in the tiny $BiO_{2-x}$ plates. The concentration of oxygen vacancy will continue to decrease because of reaction time, which is consistent with the results of EDS and XPS elements analysis.

The bandgap energies of NB-0 and NB-12 estimated from the Tauc plots [47] are 2.48 and 1.60 eV, respectively, as shown in Fig. 7(c). The valance band positions measured by VB-XPS are 1.86 and 0.82 eV for NB-0 and NB-12 (Fig. 7(d)), respectively. The room-temperature PL spectra were measured to evaluate the separation efficiency of the photo-generated electron-hole pairs. In general, a decrease in the PL intensity indicates a

suppressed electron-hole pair recombination [48]. As shown in Fig. 7(e), among NB-0, NB-1.5, NB-3, NB-6, and NB-12, NB-0 and NB-12 show the highest and lowest PL peak intensity, respectively. This result indicates that $BiO_{2-x}$ has a much better charge separation property than the starting material NBH. Consistently, NB-1.5, NB-6, and NB-3 show a gradually reduced PL peak intensity (NB-1.5 > NB-6 > NB-3) as compared with NB-0. The small vibration in the PL intensity should rise from the change in the composition ratio and the surface coverage of the composite. Besides, NB-16 and NB-21(not shown here) have no obvious difference with NB-12. Hence, the local electric field intensity of NB-12 to NB-21 is characterized by the steady-state surface photovoltage spectroscopy in Fig. 7(f). The highest SPV signal in NB-12

indicates the best charge separation efficiency [49], which can be attributed to the richer oxygen vacancy content in this sample. As a result, the photocurrent densities of NB-3 and NB-12 appear 2-fold higher than that of NB-0 and NB-16 (21), respectively, as shown in Fig. S2 (in ESM).

The performance of all samples was evaluated through the photocatalytic degradation of anionic dye MO. Figure 8(a) suggests that NB-0 has the lowest photo-catalytic performance, with only 40% MO degraded within 120 min. On the other hand, NBH/BiO$_{2-x}$ composites possess obviously improved degradation efficiency, with NB-3 showing the best photocatalytic ability. This observation is consistent with the PL characterization results shown in Fig. 7(e), indicating that the effective separation of charge carriers dominates the photocatalytic efficiency. In addition, the enhanced light absorption ability induced by BiO$_{2-x}$ in the composite can also promote the generation of more carriers. Of the three BiO$_{2-x}$ samples, i.e., NB-12, 16, and 21, NB-12 has the highest degradation rate, even higher than all other NBH/BiO$_{2-x}$ composites (Fig. 8(b)). The superior photocatalytic ability in BiO$_{2-x}$ can be probably attributed to the better light absorption with the higher photocurrent density and richer content of oxygen vacancy with a better adsorption ability. Figure S3 shows the adsorption capacities of NB-0,

NB-3, NB-12, NB-16, and NB-21 to methyl orange in the equilibrium step under dark. BiO$_{2-x}$ presents a stronger adsorption ability than NBH, which may be caused by the charge environment on the surface or a larger specific surface area. BiO$_{2-x}$ with richer oxygen defects shows a slightly higher adsorption ability than the other two. The degradation efficiencies were analyzed in more detail using quasi-first-order kinetic calculation with

$$\ln(C_0/C_t) = kt,$$

where $k$ is the quasi-first-order rate constant, $C_0$ is the equilibrium concentration of MO, and $C_t$ is the concentration at time $t$. Interestingly, NB-3 and NB-12 show the two dominant peaks in the degradation rate as plotted in Fig. 8(d), consistent with the investigations from PL, SPV, and photocurrent characterizations.

The above observations suggest that the light absorption ability, morphology, gradient composition, and the concentration of oxygen vacancies should affect the production of electrons and holes, exposed active sites, the charge separation at the hetero-interface, and intrinsic properties, which in turn determine the photocatalytic performance. In the NBH/BiO$_{2-x}$ composite, the proper band positions of NBH and BiO$_{2-x}$ support the transfer of electrons from BiO$_{2-x}$ to NBH, and the induced holes from NBH to

BiO$_{2-x}$ (Fig. 9(a)). The NBH conduction band has a more negative reduction potential than O$_2$/couple, which can support the generation of O$_2^{-\bullet}$ or be further converted into ·OH. In addition to the photogenerated holes on the valence band of BiO$_{2-x}$, the reactive oxygen radicals could also support the degradation of methyl orange. As shown in Fig. 10(a), the scavenger test results of NB-3 prove the existence and function of reactive oxygen radicals and holes, in the measurements, the O$_2^{-\bullet}$, ·OH and h$^+$ species were captured by using Benzoquinone, isopropyl alcohol and EDTA-2Na, respectively. Among all NBH/BiO$_{2-x}$ composites, NB-3 seemed to possess the optimized morphology and gradient composition, which leads to more available reaction sites and a more efficient charge separation. However, in the case of NB-6, as shown in the SEM image, the NBH sheets are mostly covered by BiO$_{2-x}$, hence, the reactive sites on the component of NBH could not expose to the reactive species, resulting in a bad photocatalytic performance. After NB-6, both NBH and BiO$_{2-x}$ are exposed, resulting in the recovery of the photocatalytic performance. In BiO$_{2-x}$ samples, the surface

oxygen vacancies in BiO$_{2-x}$ could act as catalytic centers as shown in Fig. 9(b). The photogenerated electrons can be captured in oxygen vacancy, and participate in the rapid activation of O$_2$ to O$_2^{-\bullet}$ [50,51]. Furthermore, the oxygen vacancy could promote more adsorption of anionic molecular on the surface of BiO$_{2-x}$, which also helps in improving the degradation of MO. The scavenger test results of NB-12 in Fig. 10(b) also proves the existence and function of reactive oxygen radicals and holes. However, in the test of holes, the EDTA-2Na may also be adsorbed on the surface of the catalyst and block the active sites, resulting in a huge drop in degradation performance. Both NB-3 and NB-12 show a good stability as shown in Fig. S4 (in ESM). The recycle experiments show that the degradation efficiencies remain relatively stable. There is no obvious change between the XRD patterns of fresh and used samples. Based on the obtained investigations, the degradation efficiency and photocurrent decreases with the decrease of the concentration of oxygen vacancy in BiO$_{2-x}$. It can be inferred that BiO$_{2-x}$ formed with different reaction times should present different photocatalytic

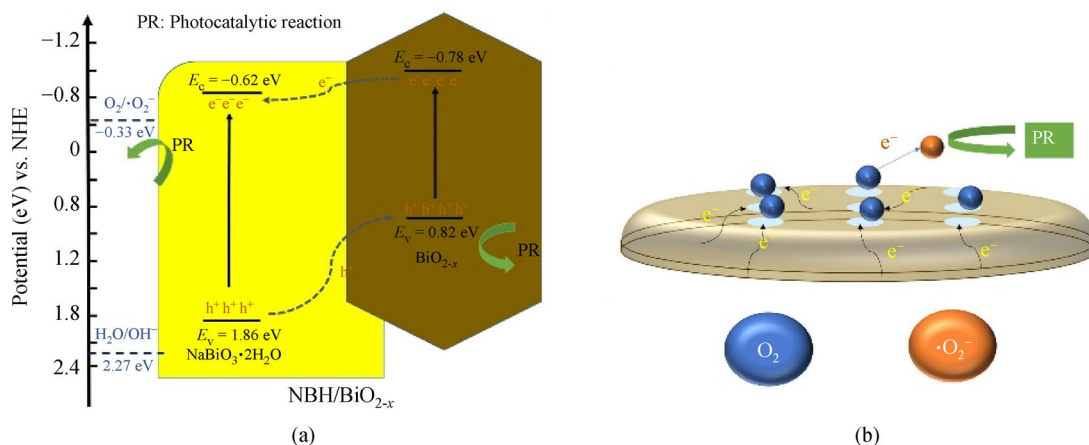

**Fig. 9**  Mechanism of photocatalytic degradation process.

properties, due to the evolution of the oxygen vacancy. Consequently, to construct a composite system, not only the fraction and distribution of each component, but also the property evolution of each component during the coupling process should be considered. Based on the SEM, XRD, and XPS characterization results, the phase transition process based on the structure and reaction time is manifested in Scheme 1.

Furthermore, to investigate the photocatalytic reduction abilities of the NB-3 composite and $BiO_{2-x}$, the measurements of photocatalytic $CO_2$ reduction in a solid/gas system were conducted. The main product of all the measurements is CO gas, as shown in Fig. 11, where very small amount of $CH_4$ can be observed. The performance of sample NB-3 is higher than that of NBH regarding the CO production rate, which is consistent with the trend observed in the degradation test. It could be attributed to the stronger light absorption ability and efficient separation of electrons and holes in NB-3. Interestingly, the $BiO_{2-x}$ (NB-12) shows a poor performance in the photoreduction

of $CO_2$. This should be attributed to the surface of $BiO_{2-x}$ which is not conducive to the reduction of $CO_2$. Therefore, for a photocatalyst, the surface activity to different reactants also directly affects the catalytic performance. The investigation of surface activity will be performed in future work.

## 4   Conclusions

An *in situ* phase transition process under hydrothermal reaction is proposed. This process is helpful to analyze the factors that affect the catalytic performance in a composite. In the gradient phase transition process from NBH to $BiO_{2-x}$, determined by the reaction time, the fraction and distribution between NBH and $BiO_{2-x}$ in the NBH/$BiO_{2-x}$ composite directly affect the morphology. A proper amount of $BiO_{2-x}$ on the surface of NBH could effectively suppress the electron/hole recombination and increase the exposed reactive sites for photocatalytic reaction. A fully
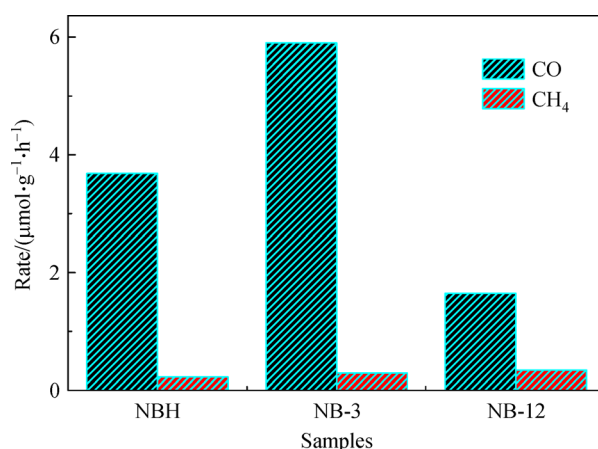

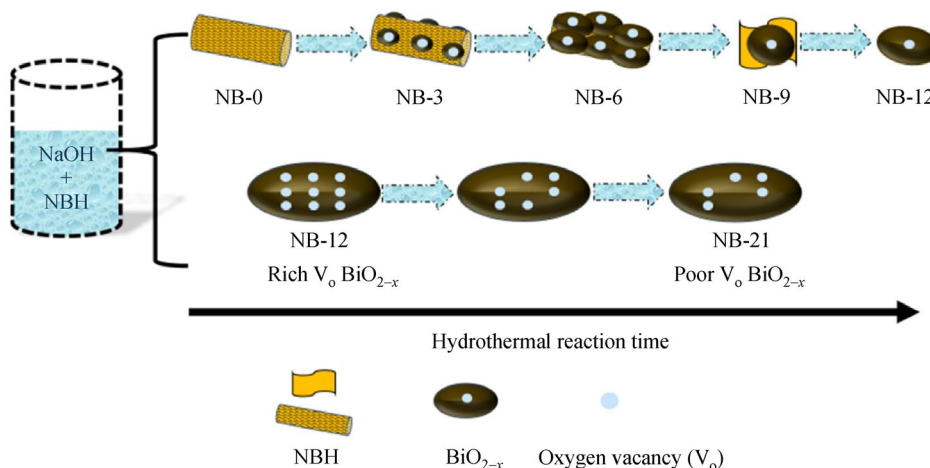

**Fig. 11**   Photocatalytic conversion rates of $CO_2$ to CO and $CH_4$ based on the samples of NBH, NB-3, and NB-12.

**Scheme 1**   Phase transition process based on the structure and reaction time.

covered $BiO_{2-x}$ on $NaBiO_3 \cdot 2H_2O$ results in a dramatical decrease of photocatalytic performance, due to the inhibited reactive sites. An over long hydrothermal process can result in $BiO_{2-x}$ with a reduced oxygen vacancy, which degrades the photocatalytic activity. This phenomenon reveals that the defects in $BiO_{2-x}$ could be affected by the process of constructing a $BiO_{2-x}$ based composite. This study presents clear information of the factors that can affect the photocatalytic performance. It also illustrates that in addition to selecting gradient materials with suitable bandgap structures, the composition and morphology, the evolution of oxygen vacancy content or defect in a component is also an important factor that should be optimized to achieve high photocatalytic efficiency.
